SUMMARY

GDE1 is a mammalian glycerophosphodiesterase (GDE) implicated by in vitro studies in the regulation of glycerophosphoinositol (GroPIns) and possibly other glycerophospho (GroP) metabolites. Here, we show using untargeted metabolomics that GroPIns is profoundly (>20-fold) elevated in brain tissue from GDE1(−/−) mice. Furthermore, two additional GroP metabolites not previously identified in eukaryotic cells, glycerophosphoserine (GroPSer) and glycerophosphoglycerate (GroPGate), were also highly elevated in GDE1(−/−) brains. Enzyme assays with synthetic GroP metabolites confirmed that GroPSer and GroPGate are direct substrates of GDE1. Interestingly, our metabolomic profiles also revealed that serine (both L- and D-) levels were significantly reduced in brains of GDE1(−/−) mice. These findings designate GroPSer as a previously unappreciated reservoir for free serine in the nervous system and suggest that GDE1, through recycling serine from GroPSer, may impact D-serine-dependent neural signaling processes in vivo.

INTRODUCTION

The glycerophosphodiester phosphodiesterases (GDEs) are an ancient and ubiquitous family of enzymes with numerous members found in all three domains of life. These enzymes are metal-dependent phosphodiesterases that cleave the phosphodiester bond of various glycerophosphodiester (GroP) metabolites, such as the deacylated phospholipids glycerophosphocholine (GroPCho) and glycerophosphoinositol (GroPIns), to release glycerol-3-phosphate (G3P) and the corresponding head-group alcohol. Several prokaryotic GDEs have been characterized and shown to be necessary for catabolism of environmental GroP metabolites, suggesting a role for these enzymes in phospholipid remodeling and nutrient scavenging (Larson et al., 1983; Tommassen et al., 1991). Transporters for GroP metabolites have also been identified in microbes and mammals, indicating that dedicated systems exist for GroP-metabolite uptake and catabolism (Fisher et al., 2005; Mariggio et al., 2006; Patton-Vogt and Henry, 1998).

Following the characterization of microbial GDEs, a group of mammalian GDEs was identified that contains seven members (GDE1-7) with diverse patterns of expression (Yanaka, 2007). In contrast to microbial GDEs, which are predominantly periplasmic or cytoplasmic, six of the seven mammalian GDEs are membrane bound and possess multiple membrane-spanning domains, suggesting that their functions may have diverged significantly from their prokaryotic ancestors. The physiological roles ascribed to mammalian GDEs are diverse. GDE2 has been shown to regulate motor neuron differentiation by a mechanism that depends on the integrity of its catalytic residues (Rao and Sockanathan, 2005; Yan et al., 2009), and a separate report implicated GDE2 in the regulation of GroPCho levels in the kidney (Gallazzini et al., 2008). GDE3 has been found to promote osteoblast differentiation upon transient overexpression (Yanaka et al., 2003). Recently, GroPIns was identified as a substrate for GDE3, and, interestingly, GDE3 displays phospholipase C-type activity (releasing inositol-phosphate and glycerol) rather than the D-type phospholipase activity exhibited by other characterized GDEs (Corda et al., 2009a). Finally, GDE1 has been shown to interact with regulators of G protein signaling (Zheng et al., 2003), and its catalytic activity can be modulated by stimulation of G protein-coupled receptors (Zheng et al., 2003). GroPIns is a substrate for GDE1 in vitro (phospholipase D-type hydrolysis), and several other GroP metabolites, including GroP-serine (GroPSer) and GroP-inositol-4,5-biphosphate, can competitively inhibit the action of GDE1 on GroPIns (Zheng et al., 2003), suggesting that these GroP compounds might also be direct GDE1 substrates. Finally, we discovered that GDE1, but not other mammalian GDEs, also accepts GroP-N-acetyl ethanolamines (GP-NAEs) as substrates, implicating this enzyme in the biosynthesis of NAE transmitters, such as the endocannabinoid anandamide (Simon and Cravatt, 2008). Consistent with this premise, we have found that mice harboring a targeted disruption of the GDE1 gene display a moderate impairment in acute NAE biosynthesis (Simon and Cravatt, 2010). The extent to which
other GroP metabolites are altered in GDE1(−/−) mice, however, has not yet been examined. Here, we present a global analysis of GDE1(−/−) mice using a mass spectrometry (MS)-based metabolomics platform that measures aqueous-soluble, polar analytes, including GroP metabolites and their derivatives. We confirmed that GroPIns is a physiological substrate of GDE1 that is profoundly elevated in the central nervous system of mice lacking this enzyme. Additionally, we discovered other GDE1-regulated metabolites, including GroPSer and GroPGate, that, to our knowledge, have not yet been described as natural products in eukaryotes. Finally, our broad metabolomic profiles also revealed lower serine levels in brains of GDE1(+/−) mice, suggesting that GroPSer serves as a previously unappreciated reservoir for free serine in the nervous system.

RESULTS

Analysis of GDE1(−/−) Mice by Untargeted Metabolomics

The ability to measure and study GroPIns and its derivatives has been facilitated by the availability of 3H-inositol, which can be used to metabolically label cultured cells to track the fate of inositol-containing metabolites (Emilsson and Sundler, 1984; Falsacca et al., 1996, 1997). While this technique is powerful, it is not readily applicable to organismal studies, and is dependent on the availability and facile metabolic incorporation of radioactive standards. Consequently, comparatively little is known about GroPIns metabolism in vivo or the existence and enzymatic regulation of other GroP metabolites due to a dearth of synthetic and analytical chemistry techniques for their characterization and measurement. MS-based metabolomics has emerged as a powerful strategy to globally investigate biochemical pathways in living systems and has succeeded in assigning novel metabolites under normal phase chromatography conditions (see Table S1 available online). GroP metabolites were obtained from their respective phospholipids by alkaline hydrolysis and subsequent purification (see Experimental Procedures). We next applied our optimized extraction and LC-MS conditions to perform an untargeted comparative analysis of water-soluble metabolites from brain tissue of GDE1(+/+) and (−/−) mice. Initial full-scan LC-MS surveys in negative mode analyzed an m/z range from 100 to 1200, and the XCMS software (Benton et al., 2008; Smith et al., 2006) was used for comparative data analysis.

Structural Characterization of GDE1-Regulated Brain Metabolites

Previous studies by the Farquhar group showed that GDE1 is a GroPIns phosphodiesterase in vitro (Zheng et al., 2003). As such, we presumed that the m/z 333.0 metabolite was likely GroPIns, a premise supported by high-resolution mass spectrometry (HRMS) measurements, which assigned an exact mass value within 0.1 ppm of the expected value for GroPIns (Table S3). Chemical synthesis of GroPIns and comparison of its LC retention-time and MS/MS fragmentation pattern to the natural GDE1-regulated metabolite confirmed its identity as GroPIns (Figures 2A and 2B; Figure S1A).

In the aforementioned Farquhar study (Zheng et al., 2003), competition experiments revealed that several GroP metabolites, including GroPSer, could inhibit GroPIns hydrolysis by GDE1. These data suggested that GroPSer might also serve as a GDE1 substrate, although, to our knowledge, GroPSer had not previously been identified as a natural metabolite in eukaryotes. The monoisotopic mass of the GroPSer anion ([M-H]−) is 258.04, providing a candidate identity for the m/z 258.0 metabolite that was dramatically elevated in GDE1(−/−) brains. Preparation of GroPSer via alkaline hydrolysis of phosphatidylserine (PtdSer) yielded a molecule with an identical LC-elution profile, high-resolution mass (within 0.3 ppm), and MS/MS fragmentation pattern as the natural m/z 258 metabolite, thus confirming its identity as GroPSer (Figures 2C and 2D; Figure S1B and Table S3).

Structural assignment of the m/z 259 metabolite proved more challenging, as this mass did not match those of any known or predicted GDE1 substrates. We obtained HRMS data for this metabolite and found that the anion ([M-H]−) had an exact mass of 259.022, which suggested a molecular formula of C10H13NO7P. Searches of publicly available metabolite databases revealed that this is the chemical formula for...
inositol-monophosphates, and we thus chose inositol-1-phosphate as an initial candidate structure. However, fragmentation studies performed on the endogenous m/z 259 metabolite revealed fragment ions with m/z values of 152.993 and 171.004, which are characteristic of a glycerol-phosphate backbone (Figure 2F), and, indeed, comparison with synthetic inositol-monophosphate standards revealed that these species did not co-elute with the m/z 259 metabolite (Figure S1D). Working with the knowledge that the m/z 259 metabolite likely contains a glycerol-phosphate backbone, we surmised that the alcohol head-group could represent glyceric acid (glycerate), which would engender a small-molecule glycerophosphoglycerate (GroPGate) with an exact mass value that matches the natural metabolite within 0.2 ppm (Table S3).

Key to the ultimate structural assignment was the chemical synthesis of GroPGate as described in Experimental Procedures. In brief, starting from GroPSer, the α-amino group of serine was converted into an alcohol by diazotation in the presence of sodium nitrite to afford the carboxylic acid after hydrolysis (Lencina et al., 2008). The fragmentation of the synthetic GroPGate standard revealed an m/z 166.970 ion corresponding to the exact mass of the dehydrated phosphate adduct of the glycerate head-group (Figure 2F). An identical fragmentation pattern was obtained for the endogenous m/z 258 brain metabolite. Additionally the synthetic and natural species displayed identical LC-elution profiles (Figure 2E; Figure S1C). Together, these data indicate that GroPGate is a novel natural product of the mouse brain and a principal endogenous substrate for GDE1. It should be noted, however, that we cannot formally exclude the possibility that the m/z 259 metabolite represents GroPGate conjugated via the 20 rather than 30 position on the glycerate head-group, as it is not clear whether these two GroPGate variants would show different retention times under our chromatographic conditions. We suggest based on potential biosynthetic pathways (see Discussion) that the 30-conjugated GroPGate is a more likely structure.

Finally, it is important to note that not all detectable GroP metabolites were elevated in GDE1(−/−) mice. Peaks corresponding to GroP-ethanolamine (GroPEtn) and GroP-choline (GroPCho) were identified in our metabolomic data by comparison to synthetic standards (Figure S2 and Table S3) and displayed similar levels in GDE1(+/+) and (−/−) brains (Table 1). These findings indicate that GroPEtn and GroPCho are not endogenous substrates for GDE1, which is consistent with a previous study showing that neither GroPEtn nor GroPCho competitively inhibits GDE1 activity in vitro (Zheng et al., 2003).

Evaluation of GroP Metabolites as GDE1 substrates
We next asked whether GroPSer and GroPGate, like GroPIns, are direct substrates for GDE1. In support of this premise, the membrane proteome from GDE1-transfected cells showed significantly greater hydrolytic activity toward all three GroP
substrates compared to the membrane proteome from mock-transfected control cells (Figures 3A and 3B). Substrate assays were also performed with brain membrane proteomes from GDE1(+/+) and (−/−) mice, and much greater activity was observed in GDE1(+/+) samples for all three GroP-substrates (Figures 3C and 3D). GDE1 (either recombinant or natural) was found to hydrolyze GroP metabolites with relative efficiencies of GroPSer > GroPGate > GroPIns. Together, these studies indicate that GroPSer and GroPGate, like GroPlns, are direct substrates for GDE1.

Serine Levels Are Reduced in Brain Tissue from GDE1(−/−) Mice

Our metabolomic profiles had the potential to reveal additional biochemical changes beyond the dramatic elevations in GroP metabolites caused by GDE1 disruption. A survey of known
polar metabolites, including amino acids and nucleosides, revealed that most were unaltered in GDE1(−/−) brains (Table S4). A 1.6-fold reduction was, however, observed for the amino acid serine in GDE1(−/−) brains. Subsequent targeted analysis using selected ion monitoring and a deuterated (d3)-serine standard confirmed the significance of this 1.6-fold decrease in serine in GDE1(−/−) brains (Figure 4A). Furthermore, the addition of d3-serine as an internal standard permitted precise quantitation of absolute serine concentrations, which were found to be approximately 1.6 μmol/g brain tissue in GDE1(+/+) mice, consistent with previous measurements (Klivenyi et al., 2005; Nagata et al., 1994). To evaluate the possibility that GroPSer serves as a metabolic precursor to serine in the brain, we compared the magnitude of the GroPSer elevation with the reduction in serine observed in GDE1(−/−) mice. The synthesis of isotopically labeled GroP metabolites was impractical so we compared the ionization of endogenous GroP metabolites to standard curves generated with synthetic, unlabeled GroPs (using d3-serine as a normalizing internal standard) to give estimates of endogenous GroP levels in GDE1(+/+) and (−/−) brains. We found that the absolute levels of GroPSer, GroPGate, and GroPIns were 933, 1426, and 647 nmol/g in GDE1(−/−) brain and 8, 5, and 26 nmol/g in GDE1(+/+) brain (Table 1). Thus, in GDE1(−/−) brain, the absolute elevation in GroPSer levels (−900 nmol/g increase) is roughly “mass-balanced” by the reduction in corresponding serine levels (−650 nmol/g decrease), lending support to a model where ~40% of free serine is generated from GDE1-catalyzed hydrolysis of GroPSer.

Serine exists in both L- and D-enantiomers in brain, and the latter metabolite serves as a neurotransmitter that activates NMDA receptors (Mothet et al., 2000; Snyder and Kim, 2000). We therefore asked whether L- and D-serine were similarly altered in GDE1(−/−) brains. To answer this question, we derivatized both enantiomers of serine with the chiral coupling part-ner N-(N-a-t-Boc-phenylalanyloxy)succinimide (BocPheOSu) to

**Figure 3. GroPSer, GroPIns, and GroPGate Are Direct Substrates of GDE1**

Membrane preparations from GDE1-transfected COS-7 cells (A and B) or mouse brain samples (C and D) were tested for activity against synthetic GroP metabolites with different head-groups : serine (GroPSer), glycerate (GroPGate), or inositol (GroPIns). Enzyme activity was determined by quantification of the release of free head group (serine, glycerate, and inositol from GroPSer, GroPGate, and GroPIns, respectively) by LC-MS in recombinant GDE1 assays. For mouse brain samples, enzyme activity against GroPSer and GroPGate was measured in the same way, and, for GroPIns, was determined by measuring reductions in consumed substrate (due to the presence of high background isobaric mass signals for inositol in brain samples). All assays were performed with n = 3, **p < 0.01; *p < 0.05, Student’s t test. (B) and (D) show western blots using an anti-Myc antibody (B) or rabbit polyclonal antibodies raised against recombinant mouse GDE1 (D).
generate diastereomers that could be separated by HPLC (Figure 4B). Derivatization of brain extracts with BocPheOSu confirmed that both L- and D-serine are decreased by 1.6-fold in GDE1(−/−) brains. Thus, GDE1(−/−) mice have constitutively lower brain levels of the neuroactive substance D-serine.

**DISCUSSION**

GroP metabolites are thought to be formed by the action of A/B-type phospholipases on membrane phospholipids, which generate free fatty acids and water-soluble glycerol phosphodiester. It has been shown in yeast that deacylation of phosphatidyicholine (PtdC) by a B-type phospholipase (Nte1p, the ortholog of mammalian neuropathy target esterase) yields GroPCho, which is catabolized by Gde1p (YPL110c) in a pathway that is important for PtdC recycling (Dowd et al., 2001; Patton-Vogt, 2007). Less is known about the existence of other GroP metabolites or how they are enzymatically formed and degraded in mammalian cells. This is an important problem not only from the perspective of basic metabolism, but also signaling, since GroPIns and its phosphorylated derivatives are dynamically regulated by various cell stimuli and have been shown to impact processes such as cancer invasion and cytoskeletal remodeling (for review, see Corda et al., 2009b). The development of robust methods to measure GroP metabolites in complex biological systems is critical to any effort aimed at characterizing mammalian enzymes involved in GroP metabolism.

In this study, we established an LC-MS-based metabolomics platform capable of detecting a wide range of aqueous-soluble, polar analytes, including monosaccharides, nucleosides, amino acids, and GroP metabolites. We used this platform to characterize the polar metabolome of brains from mice lacking the glycerophosphodiesterase GDE1. Previous studies have shown that GDE1 acts as a GroPIns phosphodiesterase in vitro (Zheng et al., 2003), and, accordingly, we observed dramatic (>20-fold) elevations in brain GroPIns from GDE1(−/−) mice. These findings confirm that GroPIns is a physiological substrate for GDE1 in vivo.

Because our metabolomic profiling was performed in an untargeted manner, we also observed several other changes in the polar metabolome. Most striking were two additional metabolites that displayed large-magnitude elevations in GDE1(−/−)}
brains and showed evidence of belonging to the GroP class of metabolites by MS/MS fragmentation. Chemical synthesis and comparison with standards revealed that these two substances were GroP metabolites with serine and glyc erate head-groups (GroPSer and GroPGate, respectively). To our knowledge, neither GroPSer nor GroPGate have been previously reported as natural products in eukaryotes. This may be rationalized, at least in part, by the low levels of GroPSer and GroPGate found in GDE1(+/+) mice (<10 nmol/g brain tissue). These results thus underscore one of the attributes of performing metabolomics on enzyme-disrupted systems, which has the potential to discover new metabolites that are too rare to detect in wild-type models. In contrast, other GroP metabolites, including GroPEtn and GroPCho, were not substantially altered in GDE1(−−) mice. These results indicate that GDE1 plays a broad, but not exclusive role in regulating the “GroP metabolome,” which appears to be much larger and more chemically diverse than previously appreciated.

Beyond the GroP metabolome, we also observed a ~40% reduction in free serine in GDE1(−−) brains. Quantitation of the absolute magnitudes of serine reduction and GroPSer elevation indicate that these changes are mass-counterbalanced, suggesting that GroPSer serves as a hitherto unappreciated metabolic precursor to serine in the mammalian brain. The biosynthesis and physiological role of serine in the nervous system is a research topic of much interest. Serine is classified as a nonessential amino acid because most eukaryotic cells contain the enzymes necessary to biosynthesize it from 3-phosphoglycerate. In contrast, it was recently discovered that one of these enzymes, 3-phosphoglycerate dehydrogenase (3PGDH), is downregulated in neurons compared to astroglia, where it is highly expressed (Yamasaki et al., 2001). Cerebellar Purkinje neurons, in particular, lack detectable 3PGDH and therefore cannot synthesize serine de novo (Furuya et al., 2000; Yamasaki et al., 2001). These findings have led to a model wherein serine is classified as a neurotrophic factor that is likely supplied by proximal glia in vivo. Our data point to an important role for GDE1 in maintaining the homeostatic balance of serine in the nervous system. Intriguingly, GDE1 appears to be highly expressed in Purkinje neurons (Figure S3), suggesting that this enzyme may provide certain neuronal populations with the ability to scavenge serine from the interstitial space by catabolizing GroPSer.

The biosynthesis of GroPSer itself is likely the result of A/B-type phospholipase activity on membrane phospholipids. As phosphatidylserine is localized exclusively on the inner-leaflet of the plasma membrane (Martin et al., 1995), the resulting GroPSer is presumably released into the cytosol whereupon it must be transported outside the cell by transporters (Mariggiò et al., 2006; Patton-Vogt and Henry, 1998) prior to exposure to GDE1, whose catalytic domain faces the luminal/extracellular side of the membrane (Figure 4D) (Zheng et al., 2003). The resulting free serine generated by GDE1 may be taken up by neurons and utilized directly, or taken up by glia for conversion to D-serine by serine racemase (Mothet et al., 2000; Wolosker et al., 1999; Yamamoto et al., 2003).

Serine is also of special relevance to the nervous system because its D-enantiomer is an endogenous coagonist of brain NMDA receptors (Mothet et al., 2000; Snyder and Kim, 2000). Interestingly, Ca2+-mediated release of D-serine from astrocytes is required for NMDA receptor-mediated long-term potentiation at nearby excitatory synapses (Henneberger et al., 2010). We found that both L- and D-serine are reduced by approximately 40% in the brains of GDE1(−−) mice. While these mice are overtly normal, it may be interesting to look for more specific differences in nervous system function and behavior, as serine racemase(−−−−) mice, which lack D-serine, show elevated anxiety (Basu et al., 2009) and are resistant to various forms of neurotoxicity (Inoue et al., 2008). Additionally, several neurological disorders are caused by extreme serine deficiency in humans owing in part to loss of D-serine (de Koning and Klomp, 2004).

The biosynthetic origin(s) of GroPGate are more perplexing. Whereas the deacetylation of membrane phospholipids to form GroP metabolites is a well-documented phenomenon (Emilsson and Sundler, 1984; Murray and McMaster, 2005; Simon and Cravatt, 2006), the existence of a suitable phospholipid precursor for GroPGate via deacetylation (e.g., phosphatidylglycerate) has not been reported. As such, GroPGate may be produced through another mechanism, possibly metabolic conversion from GroPSer.

In conclusion, we have shown using an untargeted metabolomics approach that GDE1 regulates several GroP metabolites in the mammalian brain, including GroPlns, GroPSer, and GroPGate. All three metabolites were subsequently verified to be direct substrates of GDE1 in vitro. Because the catalytic domain of GDE1 faces the extracellular side of the membrane (Zheng et al., 2003), our findings indicate that these metabolites likely transit through the interstitial space in the brain, raising the intriguing possibility that they may serve as signaling molecules in their own right, a possibility consistent with some of the proposed functions of GroPlns and its phosphorylated derivatives (Corda et al., 2009b). Further investigation of the potential metabolic and signaling functions of GroP metabolites will benefit from the availability of animal models, such as GDE1(−−−−) mice, that have substantial alterations in the GroP metabolome.

**SIGNIFICANCE**

Glycerophosphodiesterases (GDEs) catalyze the hydrolysis of the phosphodiester bond in glycerophospho (GroP) metabolites. Numerous GDE enzymes have been characterized in prokaryotes, but it is only recently that we have begun to appreciate the roles played by these enzymes in mammals. Here, we have characterized the polar metabolome of mice bearing a targeted disruption in the GDE1 gene. This represents the first unbiased attempt to identify the physiological substrates of a GDE enzyme in a eukaryotic organism. By applying an untargeted LC-MS-based metabolomic profiling technique, we found that GroP-inositol (GroPlns), a known in vitro substrate for GDE1, is dramatically elevated in the central nervous system of GDE1(−−−−) mice, as were two other metabolites. Analytical and synthetic chemistry methods were used to elucidate the structures of these metabolites as GroP-serine (GroPSer) and GroPG-glycerate (GroPGate), neither of which, to our knowledge, have been previously described as natural products in eukaryotes. All three GroP metabolites were confirmed to...
be direct GDE1 substrates. Our untargeted metabolomic profiles also revealed a 40% reduction in free serine levels in the brain of GDE1(+/−) mice. Interestingly, this reduction was similar in magnitude to the corresponding elevation in GroPSer in these animals, indicating that GroPSer may serve as a metabolic reservoir for serine in the central nervous system. Subsequent derivitization studies demonstrated that this 40% reduction was observed for both L- and D-serine, a significant result given that the latter amino acid is a neurotransmitter involved in long-term potentiation and neuroprotection. Taken together, these findings indicate that the mammalian “GroP metabolism” is quite diverse in structure and function and designate GDE1 as one of its principal enzymatic regulators in vivo.

**EXPERIMENTAL PROCEDURES**

### Metabolome Preparation

For the isolation of water-soluble metabolites a methanol-water extraction protocol was used, essentially as previously described (Rabinowitz and Kimball, 2007). In brief, male GDE1(+/+) and (−/−) mice (8–12 weeks old) were sacrificed and tissue was isolated and flash frozen in liquid nitrogen. Frozen brains were weighed and placed into a dounce tissue homogenizer with 1.5 ml ice-cold 80:20 CH3OH:water and homogenized with 10 strokes of the pestle. Each sample was sonicated and centrifuged at 10,000 g for 30 minutes.

### LC-MS

Tissue metabolome samples were analyzed using an Agilent 1100 LC-MSD SL instrument with ionization achieved via electrospray ionization (ESI). The scan range was set to 100–1200 Da with a source voltage of 3.0 kV. The fragmentor voltage was set to 100 V, and the skimmer voltage was set to 64 V. The collision energy was set at 35 V. Data were collected using a mass range of 100–1200 Da with 80:20 CH3OH:water and centrifuged once again. The combined supernatant separate insoluble material. The resulting pellet was re-extracted with 500 l.

### Preparation and Purification of GroPIns, GroPSer, and GroPEtn

To obtain GroPIns, GroPSer, and GroPEtn, commercially available phosphatidylinositol, phosphatidylserine, and phosphatidylethanolamine were hydrolyzed according to the following procedure. In a 4 ml glass vial provided with a magnetic stirring bar 25 mg phospholipid was dissolved in 3 ml 2:1 CHCl3:CH3OH and, after complete hydrolysis was observed (usually after 1–2 hr), the reaction was neutralized by the addition of 1 ml 2 N HCl. To separate the desired GroP products from the liberated free fatty acids the reaction mixture was extracted twice with 2 ml of water. The combined aqueous phases were washed with 2 ml CHCl3, frozen in liquid nitrogen, and lyophilized over night.

To separate the crude product from small molecules by-products and inorganic salts gel filtration chromatography was performed by dissolving the lyophilate in a minimum amount of water and passing it over a column packed with Sephadex LH-20 material (Sigma Aldrich) using 80:20 MeOH:water as mobile phase to obtain the desired products.

### Chemical Synthesis of bis[(2,2-Dimethyl-1,3-Dioxolan-4-yl)Methyl] Phosphyl Phenol

To a solution of phenyl dichlorophosphate (600 µl, 4.0 mmol) in 20 ml dichloromethane and DIEA (4 ml) at 0 °C, solketal (930 µl, 7.5 mmol) was added dropwise and the reaction was stirred at room temperature for 3 hr. Phosphate buffer (pH 7) was added to a reaction mixture, and the reaction was stirred for additional 1 hr to hydrolyze extra phenyl dichlorophosphate. After an addition of dichloromethane, organic layer was collected, and further washed with phosphate buffer (pH 7) three times to give bis[(2,2-dimethyl-1,3-dioxolan-4-yl)methyl] phenyl phosphonate (935 mg, 62%).

### Chemical Synthesis of GroPGate

To a solution of glycerophosphoserine (GroPSer) (26 mg, 100 µmol) in 0.5 N HCl (2 ml) was added NaNO2 (15 mg, 220 µmol) at 4 °C with stirring. After 12 hr, 100 µl NaOH were added and the reaction mixture was flash frozen with liquid nitrogen and lyophilized over night. The resulting white solid was dissolved in a minimum amount of water and purified using Sephadex LH-20 gel filtration material as described above affording GroPGate as a white solid.

### Analysis of D- and L-Serine Levels in Brain Tissue

To effect the transformation of the serine enantiomers into diastereomers by derivatization with N-(N-α-L-Boc-phenylalaninoyloxy)succinimide (BocPheOSu) D-serine, L-serine or a mixture thereof (104 µg, 1 µmol) was dissolved in

---

**Table S4**: High mass-accuracy measurements of Table S4 were obtained via Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometry using an Apex II 7.0T FT-ICR mass spectrometer (Bruker Daltonics, Billerica, MA) coupled to an Agilent 1100 LC system. This system is equipped with a custom electro spray source with two nebulizers for dual spray ionization enabling operation in “lock-mass” mode via the constant infusion of three compounds (omeprazole at 344.1074 m/z, hyremecromone sulfate at 254.9986, and indoxyl sulfate at 212.0023) for internal calibration. A 1 megaword file size was used resulting in an acquisition time of 0.9 s per spectrum. Using these parameters, 247,000 resolving power was achieved at 259 m/z.
500 μl PBS and BocPheOSu (10 mg, 25 μmol) was added. After stirring at room temperature for 3 hr the reaction mixture was directly analyzed by LC-MS on an Agilent Eclipse XDB-C18 column (5 μm, 4.6 mm × 150 mm). Mobile phase A consisted of 95:5 water and methanol, with 0.1% of 28% ammonium hydroxide, and mobile phase B consisted of 60:55:5 2-propanol, CH₃OH, and water, with 0.1% of 28% ammonium hydroxide. The gradient started at 5% B and then linearly increased to 45% B over 40 min followed by 100% B for 10 min at a flow rate of 0.5 ml/min. In this way the retention times of Boc-PheOSu-derivatized D- and L-serine were determined. For serine level analysis in brains, tissue samples were prepared and metabolites were extracted as described above. The resuspended metabolome (10 μl of the 50 μl resuspension) was derivatized with BocPheOSu following the derivatized metabolite mixture was analyzed by reverse-phase LC-MS as described above.

Enzyme Assays
Enzyme assays were performed with LC-MS by observing the formation of serine and glycerate in the cases of GroPser and GroPGate, and by observing formation of isositol (for recombinant GDE1 assays) or reduction of substrate (for mouse brain samples) in the case of GroPins. For recombinant GDE1 assays an N-terminal Myc-fusion of GDE1 was transiently overexpressed in COS-7 cells and membrane fractions prepared as described previously (Simon and Cravatt, 2008). The membrane samples were resuspended in assay buffer (50 mM Tris, 2 mM MgCl₂ [pH 8.0]). Assays were carried out in 100 μl total reaction volume. For each reaction 200 μM of substrate was incubated with a final concentration of 0.1 mg/ml cell-lysate or 0.5 mg/ml mouse brain membrane preparation respectively. Reactions were incubated at 37 °C for 3 hr (in the case of GroPser and GroPGate) or 9 hr (in the case of GroPins) before quenching with 1.0 ml CH₃OH. Subsequently, 25 μmol of D₂-serine were added to each reaction as an internal standard. Samples were centrifuged at 1400 x g for 3 min, and dried down under vacuum. For normal phase LC-MS analysis samples were resuspended in 30 μl water and injected into an Agilent 1100 LC-MSD SL instrument applying the following gradient: 15%–90% buffer B over 15 min followed by isocratic flow with 100% B for 5 min at a flow rate of 0.5 ml/min. For each run the injection volume was 30 μl. Each assay was conducted with an n = 3.

SUPPLEMENTAL INFORMATION
Supplemental Information includes three figures and four tables and can be found with this article online at doi:10.1016/j.chembiol.2010.06.009.
